ABSTRACT

This thesis combines Linear Optimization with Constraint Learning to optimize wind turbine placement for maximum performance in a predefined area under randomly distributed wind. A Neural Network is trained on simulated data to model the impact of turbine positioning on power output. This model is integrated as a constraint in a linear optimization problem, and the problem evaluated for a current state-of-the-art wind farm configuration.

INTRODUCTION

With the clean energy transition currently taking place in europe with ambitious targets for 2030 and beyond [4], wind energy is playing a central role in that transition, with wind energy expected rise to 50 % in the EU energy mix. [3] With wind energy thus expected to become the main contributor to the EU's energy production and large potentials identified for both onshore and offshore parks [1] attempts to optimize all parameters of windparks with even minor power efficiency improvement can be expected to yield significant returns in absolute power due to the scale of future wind energy production.

As a contribution to increasing power efficiency on future wind farms, this thesis is dedicated to a new approach for optimizing the placement of a fixed number of wind turbines in a predefined area (typically a square). To solve this optimization problem, an extension to the pyomo python library is used, that allows the introduction of Neural Networks to the optimization problem as constraints. [2] This extension allows for introducing a Neural Neural Network to model the effects of wind turbine placement relative to each other on power production for the respective windturbines. Introducing this model to the optimization problem defined in pyomo then allows for the optimization of overall power productions across all wind turbines in the wind park. The optimization problem in its simplest form can be defined as

$$\max_{\mathbf{x}, \mathbf{y}} \sum_{i=1}^n f_{Power, NN}(x_i, y_i; \mathbf{x}, \mathbf{y}) \quad (1)$$

$$\text{s.t. } X_{\min} \leq x_i \leq X_{\max}, \quad \forall i \in \{1, \dots, n\} \quad (2)$$

$$Y_{\min} \leq y_i \leq Y_{\max}, \quad \forall i \in \{1, \dots, n\} \quad (3)$$

$$\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} \geq d_{\min}, \quad \forall i \neq j \quad (4)$$

where:

- (x_i, y_i) are the coordinates of turbine i out of n total turbines,
- $f_{NN}(x_i, y_i; \mathbf{x}, \mathbf{y})$ is a neural network approximating the power output for each turbine i ,
- $X_{\min}, X_{\max}, Y_{\min}, Y_{\max}$ define the boundaries of the rectangular placement
- d_{\min} is the minimum distance between any two turbines.

To create a model optimally fit to the needs of the optimization problem, the model is trained on data specifically generated with the **FLORIS** wind farm simulation tool for optimal coverage of the parameter space of the optimization.

To simplify the problem, the surface below the turbines is assumed to be perfectly flat and equal wind speed is assumed along the entire height of the turbines.

This thesis is structured according to the two main steps required to solve the optimization problem as presented above.

STATE OF THE ART

FARM POWER MODEL

With the goal of training a model tailor made to the requirements of the optimization problem, the data used for training the model has to be generated using an open source simulation method, allowing to set the parameter space of the model as required to the given optimization problem. After investigating the two python based wind farm simulation tools FLORIS and PyWake, FLORIS was chosen due to solid documentation, what appears to be very stable releases and broad functionalities regarding wake modelling. FLORIS is a wind farm simulation tool developed by the National Renewable Energy Laboratory (NREL).

Main Effects of Wake Turbulence: - Wind Speed (needs time to mix with outside airflow) - Turbulence

3.1 DATA SOURCE

3.2 MODELLING

To model the relationship between the attributes of an incoming airflow to a wind turbine and the output generated by the same wind turbine many surrogate models could be chosen. As the model generated in this for this thesis is created with the goal of introducing it into the pyomo extension referenced in Chapter 1, the model has to be compatible with said extension. That is why the model chosen is a simple neural network with limited number of hidden layers and nodes, with the size of the Neural Network being limited for said extension.

3.2.1 *Neural Networks and Training of Neural Networks*

In the following section, a brief introduction is given into how Neural Networks work and are trained. Fundamentally, Neural Networks represent Graph Networks consisting out of Function blocks as the nodes, in the case of Neural Networks called perceptron (or Neurons as more general terms) and arcs which correspond to the inputs/outputs of a given perceptron. In simple words, the inputs to the Neurons are summed up and introduced as argument into a function $f()$ which yields an output y , representing the output of the given perceptron. These Neurons are organized in layers, which correspond to the row type structure Neural Networks are usually represented in and each perceptron of one layer is connected to every

other perceptron of the following layer. The following layer in this case means in the direction of flow, in visualizations usually from left to right. The arcs thus in simple terms correspond to a single number and the Neurons to the action of summing up all inputs and then applying the unspecified function $f()$ to generate a output. This process is repeated for all Neurons in the network, with the first layer of the network taking as input the values of the values of the given data features (the input values to the model) and the last layer producing outputs corresponding to the output value(s) of the model. The number of Neurons in this first and last layer correspond to the task the Neural Network is supposed to perform. If the goal is to identify handwritten numbers 1-9 from 50x50 pixel images, the input layer might have 50x50 Neurons for the value of each pixel, and the output layer 9 layers with the output value of each perceptron representing how much the networks thinks the given image shows the corresponding numbers 1-9. A schematic of this architecture is given in Figure 1.

Figure 1: Schematic of Neural Network Architecture

As shown in Figure 2 the output of a Neuron is slightly more complicated as described before, as the output y is generated by summing up the inputs x multiplied by a corresponding weight w together with a bias b and introducing this summation as argument into a activation function $f()$. In this process, the weights w represent a weight to give importance to the individual inputs and the bias b serves to set a minimum output value that will always be reached, regardless of the inputs.

The activation function $f()$ is called activation function, as in its most simplest form it represents a step function that decides if a neuron activates or not, e.g. takes the binary values 0, 1 for a given threshold. Contrary to the human brain where neurons are indeed binary, most Neural Networks resort to a activation function whose outputs are not binary but deliver continuous values between 0 and 1 to avoid the boundary issues that occur with binary thresholds. The most common function used instead of a step function is the sigmoid function, which roughly corresponds to a continuous version of the step function, with $\sigma(x) \approx 1$ for $x \rightarrow \infty$ and $\sigma(x) \approx 0$ for $x \rightarrow -\infty$.

Figure 2: Inputs to Output of a Neuron

$$\sigma(x) = \frac{1}{1 + e^{-x}}$$

This relationship also becomes apparent when plotting both of those functions over each other.
